

Altered microbiome composition in individuals with fibromyalgia

Amir Minerbi^{a,*}, Emmanuel Gonzalez^{b,c}, Nicholas J.B. Brereton^d, Abraham Anjarkouchian^e, Ken Dewar^{c,f}, Mary-Ann Fitzcharles^{a,g}, Stéphanie Chevalier^{e,h,i}, Yoram Shir^a

Abstract

Fibromyalgia (FM) is a prevalent syndrome, characterised by chronic widespread pain, fatigue, and impaired sleep, that is challenging to diagnose and difficult to treat. The microbiomes of 77 women with FM and that of 79 control participants were compared using 16S rRNA gene amplification and whole-genome sequencing. When comparing FM patients with unrelated controls using differential abundance analysis, significant differences were revealed in several bacterial taxa. Variance in the composition of the microbiomes was explained by FM-related variables more than by any other innate or environmental variable and correlated with clinical indices of FM. In line with observed alteration in butyrate-metabolising species, targeted serum metabolite analysis verified differences in the serum levels of butyrate and propionate in FM patients. Using machine-learning algorithms, the microbiome composition alone allowed for the classification of patients and controls (receiver operating characteristic area under the curve 87.8%). To the best of our knowledge, this is the first demonstration of gut microbiome alteration in nonvisceral pain. This observation paves the way for further studies, elucidating the pathophysiology of FM, developing diagnostic aids and possibly allowing for new treatment modalities to be explored.

Keywords: Fibromyalgia, Widespread pain, Microbiome, Gut–brain axis

1. Introduction

Fibromyalgia (FM) is one of the most common forms of chronic widespread pain, with an estimated prevalence of 2% to 4% of the adult population.^{14,30,71} Characterised by pain, physical exhaustion, sleep disturbance, and cognitive symptoms, FM leads to a significant impairment in quality of life of affected individuals.^{30,52,71,79} The pathophysiology of FM is not well understood, with multiple hypotheses being suggested including

impaired central nervous system nociceptive processing, altered peripheral nociception, and systemic inflammation.⁷⁹

The diagnosis of FM is based on the recognition of a typical cluster of symptoms, while excluding other potential sources of pain.³⁰ The diagnostic criteria for FM rely on self-reported symptoms.⁹³ The lack of objective diagnostic criteria is a source of frustration among patients and clinicians, and adds to the possible reasons for inaccurate diagnoses. In 2 retrospective cohorts of patients diagnosed with FM, the rate of false-positive diagnoses was estimated at 66% to 73%.^{22,89} Even when provided with the best available treatment, many patients continue to suffer from significant symptoms.³⁰

In recent years, evidence is mounting on the critical role of the gut microbiota in a variety of pathologies, including, but not limited to, metabolic, cardiovascular, oncologic, neurologic, and psychiatric disorders.^{33,49} The scientific literature is rich in studies on different aspects of the interactions between the host and the microbiome; however, data on the possible role of the gut microbiota in the pathophysiology of chronic pain outside of the gastrointestinal tract is still scarce. Our increasing understanding of the interactions between the gut microbiota and the central nervous system, also known as the “gut–brain axis,” makes reasonable the hypothesis that it may also affect pain processing and perception.^{6,7,15,21,24,53} Recently, this hypothesis has been supported by several animal studies, which have shown that gut microbiota play an important role in the development of visceral pain,^{48,64,65} of chemotherapy-induced neuropathic pain,⁷⁶ and of opioid tolerance.³⁵ Human studies have thus far focused on alterations of the gut microbiota in several visceral pain disorders, showing consistent alterations in individuals with irritable bowel syndrome (IBS)^{16,19,70,83,96} and in patients suffering from chronic dysfunctional pelvic pain.^{5,9,77} Similarly, patients with chronic fatigue syndrome (CFS), which shares some symptomatic features with FM, were shown to have altered gut microbiome

and metabolomic profiles.^{25,27,60,61} Finally, in several rheumatologic diseases, including rheumatoid arthritis and spondyloarthropathies, microbiome alterations have been reported.^{32,92,94,95}

Indirect evidence hints that the gut microbiome may be altered in FM patients: altered small intestinal permeability was reported in a cohort of FM and complex regional pain syndrome patients²⁸; in a small cross-sectional study of FM patients, a distinct urine metabolomic signature was demonstrated, which could be attributed to gut microbiome alterations.⁵¹

Despite recent reports of gut microbiome alterations in certain inflammatory rheumatic diseases, IBS, and interstitial cystitis (IC), there is still no evidence of such alterations in nonvisceral pain. Here, variation in the composition of the gut microbiome between FM patients and control participants is investigated for the first time.

2. Methods

2.1. Study design and oversight

The study took place at the Alan Edwards Pain Management Unit of the McGill University Health Centre, Montreal, and at the West Island Rheumatology Clinic, in Montreal, Quebec, Canada. The study was approved by the McGill University Health Centre, Montreal institutional review board. All participants were given a detailed explanation of the study and signed an informed consent form.

2.2. Patient recruitment and clinical evaluation

Individuals with FM and control participants were recruited as follows: patients were recruited at the Alan Edwards Pain Management Unit and at the West Island Rheumatology Clinic. Patients were contacted either by their treating physician, or by advertisements in the local media and a dedicated web site. Inclusion criteria for patients were: female sex, age 30 to 60 years, widespread pain index and symptom severity scores compatible with the 2016 diagnostic criteria for FM, and ability to provide informed consent in French or in English. Three groups of control participants were recruited: (1) first-degree female relatives of patients participating in the study were recruited as genetic controls. This group included adult women; (2) household members of patients participating in the study were recruited as environment controls. This group included women and men aged 30 to 70 years; and (3) unrelated healthy women aged 30 to 60 years.

Exclusion criteria were: major chronic illness (eg, malignancy, active inflammatory disease, and metabolic disease), antibiotic treatment in the preceding 2 months, any acute illness in the preceding month, change in regularly taken medication in the preceding month, and substantial dietary alterations in the preceding month.

All patients with chronic pain were interviewed by a specialized pain physician for a thorough assessment. Only individuals whose diagnosis of FM was confirmed were deemed eligible to participate in the study as patients. All patient and control participants were interviewed by a specialized pain physician, and data were collected regarding their demographics, anthropometrics, comorbidities (including a specific evaluation for IBS, based on ROME IV criteria^{44,55}), medications, dietary intake, smoking, and alcohol consumption. Comorbidities were recorded based on a systematic clinical interview by a pain medicine physician and a review of participants' regular medications. Participants then filled-in the following questionnaires: the FM Survey Diagnostic Criteria and Severity Scale questionnaire, assessing symptom severity, pain location, fatigue, sleep quality, and cognitive and somatic

complaints in FM patients, based on the 2016 criteria for the diagnosis of FM⁹³; the FM Impact Questionnaire, a 10-item questionnaire evaluating physical functioning, work difficulty, pain, fatigue, morning tiredness, stiffness, anxiety, and depression¹¹; physical activity assessment using the Physical Activity self-Administered Questionnaire, a 22-item questionnaire evaluating the average individual physical activity level⁹⁸; and Sleep Scale from the Medical Outcomes Study, a 12-item sleep quality evaluation questionnaire.⁵⁸ All questionnaires were offered in English or in French and have been validated in both languages.^{13,23,68,88} Participants were then interviewed by a dietitian, who supervised them as they filled-in the web-based NIH ASA24-Canada dietary recall, validated in English and in French.⁸⁶

2.3. Dietary intake assessment

Dietary intake was assessed using the NIH Automated Self-Administered 24-hour recall (ASA24-Canada version 2016, English or French). This tool has been extensively validated.^{66,86} During the on-site visit, participants were trained and supervised by a dietitian as they filled the first day of recall online. They were asked to fill 2 additional separate days during the following week, allowing for a total of 3-day dietary assessment, including 2 weekdays and one weekend day. Data sets with at least 2 complete days were kept ($n = 146$) and daily nutrient averages were calculated. Nutrient intakes were compared among groups as absolute intakes and relative to energy or body weight. Underreporting was investigated by applying a ratio of reported energy intake over resting energy expenditure estimated with the Mifflin-St. Jeor equation⁵⁶; participants with a ratio below 0.9 were deemed as underreporters and excluded from analysis. The Healthy Eating Index (HEI-2015) was calculated to assess diet quality.³⁹

2.4. Sample acquisition and handling

Patients were asked to collect a stool sample at home, using the Omnigen Gut OM-200 kit (DNA Genotek, Ottawa, Ontario, Canada). Stool was fresh-frozen at -20°C , and delivered by the participants to the study facility within 10 days of its collection. Proper delivery conditions were assured using a dedicated thermal bag (Thermos, Schaumburg, IL) containing an ice pack, and monitored using an adhesive thermal indicator (Warm Mark; MesaLabs, Lakewood, CO), which was attached to the sample bag. On arrival at the study facility, thermal indicators were read to assure proper delivery conditions, and the stool samples were frozen at -80°C .

2.5. DNA extraction, 16S ribosomal RNA gene amplification, and Illumina sequencing

DNA was extracted from all 156 stool samples using the QIAamp PowerFecal DNA kit (Qiagen, Venlo, the Netherlands) following the manufacturer's instructions. The V5-V6 region (based on *Escherichia coli*) of the 16S ribosomal RNA (rRNA) was targeted for amplification by PCR using the forward primer: S-D-Bact-0785-a-S-18, GGTTAGATACCCBDGTA and reverse primer: S-*Univ-1100-a-A-15, GGGTYKCGCTCGTTR.³⁸ The CS1 (ACACTGACGACATGGTCTACA) and CS2 (TACGGTAGCAGACTTGGTCT) tags were used to add a barcode and Illumina adapters. Amplification was performed using Q5 High-Fidelity DNA polymerase (New England BioLabs, Ipswich, MA) with PCR cycles as follows: initial denaturation step of 98°C , for 30 seconds, before 23 cycles of 98°C , for 10 seconds, 58°C , for 15 seconds, and 72°C , for 30 seconds, with the final extension at 72°C , for 2 minutes. The MiSeq250 platform was used for 2×250 nucleotides

(nt) paired-end sequencing of the resulting PCR products. The ANCHOR pipeline was used to process and annotate sequence reads (<https://github.com/gonzalezem/ANCHOR>). Briefly, sequences were aligned and dereplicated using Mothur⁷⁴ before selection of operational taxonomic units (OTUs) using a count threshold of 48 across all samples. Annotation used 4 sequence repositories with strict BLASTn criteria (>99% identity and coverage): NCBI-curated bacterial and Archaea RefSeq, NCBI nr/nt, SILVA, Ribosomal Database Project (NCBI-curated bacterial and Archaea RefSeq is given a priority when at 100% identity and coverage). When the highest identity/coverage is shared among different putative annotation, all are retained and reported (borrowed from the idea of secondary annotation in metatranscriptomics²⁹). Amplicons with low counts (<48) are binned to high-count sequences in a second BLASTn, using a lower threshold of >98% identity/coverage.

2.6. Whole-genome sequencing, analysis using MetaPhlan2, and mapping to 16S rRNA gene operational taxonomic units

Genomic DNA was quantified using the Quant-iT PicoGreen dsDNA Assay Kit (Life Technologies, Carlsbad, CA). Libraries were generated using the NEB Ultra II DNA kit (NEB) as per the manufacturer's recommendations. TruSeq adapters with unique dual indices and PCR primers were purchased from IDT (Integrated DNA Technologies, Inc, Coralville, IA). Size selection of libraries at 360 nt was performed using SPRIselect beads (Beckman Coulter, Brea, CA). Libraries were quantified using the Quant-iT PicoGreen dsDNA Assay Kit (Life Technologies) and the Kapa Illumina GA with Revised Primers-SYBR Fast Universal kit (Kapa Biosystems Inc., MA). Average size fragment was determined using a LabChip GX (PerkinElmer, Waltham, MA) instrument. The libraries were normalized, pooled, and denatured in 0.05 N NaOH and then neutralized using HT1 buffer. ExAMP was added to the mix to bring the final concentration to 200 pM following the manufacturer's instructions. A phiX library was used as a control and mixed with libraries at 1% level. The pool was loaded on an Illumina cBot, and the flowcell was run on a HiSeq 4000 for 2 × 100 cycles (150 nt, paired-end mode). The Illumina control software was HCS HD 3.4.0.38, and the real-time analysis program was RTA v. 2.7.7. Program bcl2fastq2 v2.18 was then used to demultiplex samples and generate fastq reads. Trimmomatic⁴³ was used to trim nucleotides of poor quality and reads <100 nt were removed (parameters: LEADING:25 TRAILING:25 MINLEN:100). Whole-genome sequencing (WGS) reads were analysed in 2 ways: by directly mapping them to the 16S rRNA gene ANCHOR OTU sequences and using MetaPhlan2.⁷⁵ Bowtie2⁴¹ was used to align WGS reads against MetaPhlan2 v2.2.0 (default parameters). Mapping of WGS reads directly to the ANCHOR OTU table was performed using BLASTn (100% identity and 100% query coverage thresholds).

2.7. Canonical correspondence analysis and prediction

Canonical correspondence analysis was performed on raw OTU counts of FM patients and unrelated controls (PERMANOVA, permutational multivariate analysis of variance $P < 0.001$). Household and family controls were projected on the axes post hoc (predict.cca function, R Vegan package⁶²).

2.8. Microbiome explained variance analysis

Unconstrained ordination was calculated using Nonmetric Multidimensional Scaling transformation on Bray–Curtis

distances (metaMDS function, R Vegan package). Environmental factors were projected onto ordination diagram, and each variable regression was independently tested by Monte Carlo permutation test (envfit function, R Vegan package).⁶²

2.9. DESeq2 differential abundance analysis

Differential abundance analysis was performed using 16S rRNA in accordance with DESeq2,^{47,84} which has been shown to perform well when applied to the uneven library sizes and sparsity common in 16S rRNA gene marker data.⁹¹ Differentially abundant (DA) selection parameter of false discovery rate (FDR; Benjamini–Hochberg procedure) < 0.1 was applied^{4,46,47} (supplementary file, available at <http://links.lww.com/PAIN/A839>). Regularized log transformation was applied to raw counts across samples (rlog function, R phyloseq package⁵⁴). A sparsity and low-count cutoffs were used whereby an OTU count in a single sample is <90% of the count in all samples, and OTU count must be >2 in 40% of the samples.

2.10. Correlation between taxa abundance and clinical indices

Spearman's correlation was calculated between log-transformed OTU abundance and continuous or rank clinical variables. Individual P value was calculated for comparison, and correction for multiple comparisons was done using Benjamini–Hochberg FDR, with a cutoff value of 0.05. A colour-coded correlation matrix representing taxa abundance vs clinical indices was elaborated and sorted based on hierarchical clustering of DA OTUs using MathWorks MATLAB.

2.11. Operational taxonomic unit–operational taxonomic unit correlation

Pearson's correlation was calculated between normalized OTU counts. Correlation matrices were sorted based on hierarchical clustering of OTUs and represented using R package corrplot.⁹⁰

2.12. Machine-learning instances for fibromyalgia prediction

The L1-penalized regression or LASSO (least absolute shrinkage and selection operator)⁸⁵ was used to predict FM diagnosis from the ANCHOR DA OTU count table and was run using glmnet R package.²⁶ Several count tables were tested as preselection data sets for the LASSO including full and reduced (sparsity filtered, DESeq2 DA OTUs), each with different count transformation or normalization strategies (raw, log, quantile, square root; supplementary Figure 5, available at <http://links.lww.com/PAIN/A839>). DESeq2 DA OTUs (72 features) performed better in diagnosis prediction than sparsity-filtered counts (1071 features), and so were considered a good preselection data set in line with previous research.⁹⁸ Random OTU count table subsets of equivalent size (each with ~72 OTUs) were also compared against the DESeq2 DA OTU subset, with DA OTUs again showing better prediction power (supplementary Figure 3, available at <http://links.lww.com/PAIN/A839>). Raw counts outperformed transformed data (log, square root) and normalized counts (quantile) in their prediction and were used for subsequent analysis. LASSO's integrated feature selection (ie, selection of sets of features leading to best prediction) was run on DESeq2 DA count table (72 OTUs) using a 10-fold multinomial cross-validation and repeated 10,000 times. A total of 123 high predictive DA OTU sets, ie, sets of features selected multiple times by LASSO with a high prediction

(median area under the curve [AUC] > 0.9) or selected a single time with a perfect prediction (AUC of 100%), were selected for leave-one-out cross-validation multinomial LASSO. Leave-one-out cross-validation was performed on training data sets composed of 90% of the participants and was repeated 1000 times. Prediction was evaluated on the remaining 10% of participants (test data set). Receiver operating characteristic (ROC) curves (pROC R package⁷³) were used to illustrate the discriminative ability of the classifier, whereas prediction performance was evaluated by the AUC metric. The related support vector machine (SVM) technique³⁴ was used based on the best predicting DA OTUs and 90% of the samples, and the diagnosis prediction was evaluated (AUC on 10% on the total number of participant).

2.13. Targeted serum metabolite analysis

Serum levels of butyric acid, isobutyric acid, and propionic acid were measured as previously described.¹⁷ Targeted metabolite quantification approach was used to analyze the serum samples using a combination of direct injection mass spectrometry with a reverse-phase liquid chromatography-tandem mass spectrometry (LC-MS/MS custom assay). The method used combines the derivatization and extraction of analytes, and the selective mass-spectrometric detection using multiple reaction monitoring pairs. Isotope-labeled internal standards and other internal standards are used for metabolite quantification. The custom assay contains a 96-deep-well plate with a filter plate attached with sealing tape, and reagents and solvents used to prepare the plate assay. First 14 wells were used for one blank, 3 zero samples, 7 standards, and 3 quality control samples. One hundred fifty microliter of ice-cold methanol and 10 μ L of isotope-labeled internal standard mixture were added to 50 μ L of serum sample for overnight protein precipitation. Then it was centrifuged at $\times 13,000g$ for 20 minutes. Fifty microliter of supernatant was loaded into the center of wells of a 96-deep-well plate, followed by the addition of 3-nitrophenylhydrazine (NPH) reagent. After incubation for 2 hours, BHT stabilizer and water were added before LC-MS injection.

Mass spectrometric analysis was performed on an API4000 Qtrap tandem mass spectrometry instrument (Applied Biosystems/MDS Analytical Technologies, Foster City, CA) equipped with a solvent delivery system. Data analysis was performed using Analyst 1.6.2.

2.14. General statistical considerations

Clinical indices, including demographics, anthropometrics, comorbidities, and medications, in the study groups were compared using IBM SPSS Statistics version 23 and MathWorks MATLAB version 2018b, using analysis of variance (ANOVA) for univariate comparisons and multivariate analysis of variance for multivariate comparisons. Metabolite concentrations were compared similarly.

Dietary analysis was performed as follows: normality of distribution was explored using Kolmogorov–Smirnov and Shapiro–Wilk tests. Most dietary data were assessed using one-way ANOVA and post hoc Games-Howell test (no assumption of equal variance and appropriate for unequal sample size). Some nutrients were not normally distributed and analysed using nonparametric Kruskal–Wallis test. Analyses were conducted using IBM SPSS Statistics version 23.

Formal power analysis for sample-size calculation was not performed, but sample size was not smaller than that of similar previous studies of microbiome characterization in other medical conditions.⁹⁴

2.15. Data availability

All data generated as part of this study are included in this published article and its supplementary file or are available from the corresponding authors on reasonable request. Supplementary file is available at <https://github.com/gonzalezem/Fibromyalgia>. Genome sequences can be found at <https://www.ncbi.nlm.nih.gov/sra/PRJNA521398> (16S rRNA sequences) and <https://www.ncbi.nlm.nih.gov/sra/PRJNA521587> (WGS sequences).

3. Results

3.1. Participant characteristics

Two hundred potential participants were screened for this study. Twenty-nine participants were excluded during the screening phase and 15 participants, who did not meet the diagnostic criteria for FM, were excluded following a medical interview with 2 specialized pain physicians. Of the 156 participants, 77 were FM patients and 79 were control participants. Control participants included 11 first-degree relatives of participating FM patients, 20 household members of participating patients, and 48 unrelated controls. Other than sex, marital status, and occupational status, differences in demographic and anthropometric characteristics among groups were not statistically significant (supplementary table 1, available at <http://links.lww.com/PAIN/A839>). One patient in the first-degree relative control group was diagnosed with well-controlled rheumatoid arthritis, with no evidence of active arthritis or elevated inflammatory markers. All participants were recruited and all samples collected between October 2017 and June 2018. No seasonal variation was observed between groups when comparing sample collection season (ANOVA $P = 0.30$, $F = 1.24$).

Fibromyalgia patients were women (mean age 46 ± 8 years), who on average had been diagnosed with FM 12 (SD 7.7) years earlier. The majority of participants were of Caucasian ethnicity. Mean widespread pain index in the patients' group was 11 (SD 3.2), and their mean symptom severity score was 9.3 (SD 1.8). The 2016 FM diagnostic criteria scores and FM Impact Questionnaire scores were significantly higher in patients compared with all control groups (Pillai's trace $P < 0.0001$, $F = 4.53$; supplementary table 2, available at <http://links.lww.com/PAIN/A839>). Participants' sleep quality was evaluated using the Insomnia Severity Index questionnaire. Fibromyalgia patients reported more difficulty falling asleep, maintaining sleep, and early awakening (Pillai's trace $P < 0.0001$, $F = 7.75$, see univariate analysis in supplementary table 3, available at <http://links.lww.com/PAIN/A839>). The frequency of depression and anxiety scores of 5/10 or higher among FM patients was 59% and 68%, respectively, in line with previous reports.^{2,31}

Participants' physical activity was evaluated using the Physical Activity Self-administered Questionnaire. No consistent trend towards higher or lower level of activity was observed for any group (supplementary table 3, available at <http://links.lww.com/PAIN/A839>).

Dietary assessment was performed for all participants. Among participants with complete dietary reports, 16 patients and 3 unrelated controls were excluded for underreporting. Energy and macronutrient intake (total and relative) were not different between patients and controls (supplementary table 4, available at <http://links.lww.com/PAIN/A839>). In addition, vitamin, mineral, different fatty acids, alcohol, caffeine, sugar, and fiber intakes were not different among groups, nor was overall diet quality score (data not shown).

3.2. Overall gut microbiome composition

To explore the composition of the gut microbiome of FM patients and controls, we studied a cohort of 156 adults. Stool samples (77 FM patients and 79 controls) were collected and sequenced using both 16S rRNA and metagenome methods, and analyzed at multiple taxonomic levels. 16S rRNA sequencing produced 12,137,453 reads, with an average of $77,804 \pm 6832$ reads per sample.

A total of 1620 OTUs were identified capturing 8,474,421 reads. These could be classified at various taxonomic levels: 8 at class, 25 at order, 179 at family, 716 at genus, and 349 as species, with 343 OTUs remaining as unclassified or unknown (Fig. 1). Predominant phyla across all participants included bacteroidetes (48% of total raw counts), firmicutes (40%), proteobacteria (4%), and actinobacteria (2%). From the 349 OTUs annotated at species taxonomic level, 312 were unique whereas 37 shared a sequence common to multiple species (additional 16S and WGS data are provided in the supplementary file). The 10 most abundant OTUs annotated at species resolution across all samples were from the *Bacteroides* genera, including *Bacteroides dorei*, *Bacteroides uniformis*, *Bacteroides stercoris*, *Bacteroides ovatus*, as well as *Prevotella copri*, *Alistipes putredinis*, and *Faecalibacterium prausnitzii*.

To validate the taxa identified using 16S rRNA gene amplification, WGS data were directly mapped to the 16S rRNA gene OTU table as well as analysed using MetaPhlan2. Whole-genome sequencing generated 1,289,867,794 reads with an average of 8,268,383 reads per sample. All 1620 OTUs were successfully recapitulated by WGS reads at 100% identity. The median coverage was 99.1% (SD 4.2) with 1015 OTUs mapped uniquely and 605 sharing reads. Independent analysis using MetaPhlan2 identified 196 species, including all but 3 species found using 16S rRNA gene amplification with the exception of those not yet present in the MetaPhlan2 marker database (80 species, Fig. 1H).

3.3. Gut microbiome composition is altered in fibromyalgia patients

Shannon and inverse Simpson alpha-diversity indices showed nonsignificant differences in sample diversity between FM patients and household, relatives, and unrelated control groups (ANOVA $P > 0.05$; Fig. 1F). Bray–Curtis dissimilarity between pairs of participants showed a small but significant difference in mean dissimilarity metrics among FM–FM pairs as compared to FM–control pairs ($P < 0.0001$, $F = 48.44$), or control–control pairs ($P < 0.0001$, $F = 56.71$, Fig. 1E).

Canonical correspondence analysis suggests that samples segregate by FM patients and unrelated controls in nonoverlapping clusters (Fig. 2A). Multivariate analysis showed between-group variance to be significantly greater than within-group variance ($P < 0.01$) between FM patients and unrelated controls. Household members and first-degree relative controls clustered between FM patients and unrelated controls (Fig. 2B).

Differential abundance analysis was performed to compare FM patients (77) with unrelated control participants (48) using DESeq2. Seventy-two OTUs were identified as significantly DA, 53 higher in FM and 18 higher in unrelated controls. These included 47 that could be annotated at either genera or species taxonomic levels and included taxa from firmicutes, bacteroidetes, and proteobacteria. The largest positive fold-change difference in DA putative species observed in FM patients were from the OTUs *Parabacteroides merdae*_4 and

*Clostridium scindens*_1, whereas the largest negative fold-change difference in FM patient were in *Prevotella copri*_1 and *Bacteroides uniformis*_3 (Fig. 3).

When relative abundance of OTUs were correlated, DA species generally clustered according to their abundance in participant groups, whereby species found in higher abundance in FM patients clustered together, whereas those found in higher abundance in controls clustered separately (supplementary Figure 1A, available at <http://links.lww.com/PAIN/A839>). Among DA species, the majority of correlations were statistically significant ($P < 0.1$), showing positive correlations between a majority of DA species within FM group and within unrelated control group (Pearson correlation > 0) and significant inverse correlations of DA species between FM and unrelated control groups (Pearson correlation < 0 , supplementary Figure 1B, available at <http://links.lww.com/PAIN/A839>). This observation serves as an independent support that DA taxa represent a valid difference between FM patients and controls.

To control for possible confounding effects of host-related and environmental variables, the amount of variance (r^2) explained by various possible confounders was evaluated using a general linear model. The highest amounts of microbiome variance were explained by the diagnosis of FM and disease-specific measures, whereas all other covariates, including diet, medications, comorbidities and anthropometric variables, had a smaller effect on the observed variance (see supplementary Figure 2 Tables 5 and 6, available at <http://links.lww.com/PAIN/A839>). This suggests that at least some of the observed differences in microbiome composition are likely to be attributed to FM.

3.4. Altered serum levels of fermentation end products in fibromyalgia patients

Consistent alterations in the abundance of butyrate metabolism-related bacteria were observed: *F. prausnitzii* and *B. uniformis* were found in lower relative abundance in FM patients, whereas higher relative abundance was observed for *Intestinimonas butyriciproducens*, *Flavonifractor plautii*, *Butyricoccus desmolans*, *Eisenbergiella tayi*, and *Eisenbergiella massiliensis*. To explore the possible metabolic effect of these alterations, a targeted metabolite approach was used to measure the serum concentrations of butyric acid, isobutyric acid, propionic acid, and lactic acid. Serum levels of butyric acid in FM patients ($n = 73$) were higher compared to unrelated controls ($n = 46$, $P = 0.005$), whereas levels of propionic acid were lower ($P = 0.006$) and a trend towards lower levels of isobutyric acid was also observed ($P = 0.056$). No significant differences in the serum levels of lactic acid were observed (Fig. 4B). Multivariate analysis showed a significant between-group difference (Pillai's Trace, $F = 8.97$, $P < 0.0001$).

3.5. Gut microbiome is associated with clinical indices of fibromyalgia

To explore the relationship between DA taxa abundance and symptom severity, the relative abundance of DA OTUs was correlated against disease-specific and independent variables. Spearman's rank correlation coefficient demonstrated a statistically significant association between the abundance of several taxa and disease severity measures, including pain intensity, widespread pain index, dyscognition, and fatigue (Benjamini–Hochberg FDR < 0.05 , Fig. 4A). The abundance of these taxa showed no consistent relationship with patients' demographic, anthropometric, or physical activity variables. Thus, abundance of some DA taxa could be correlated with FM symptom severity.

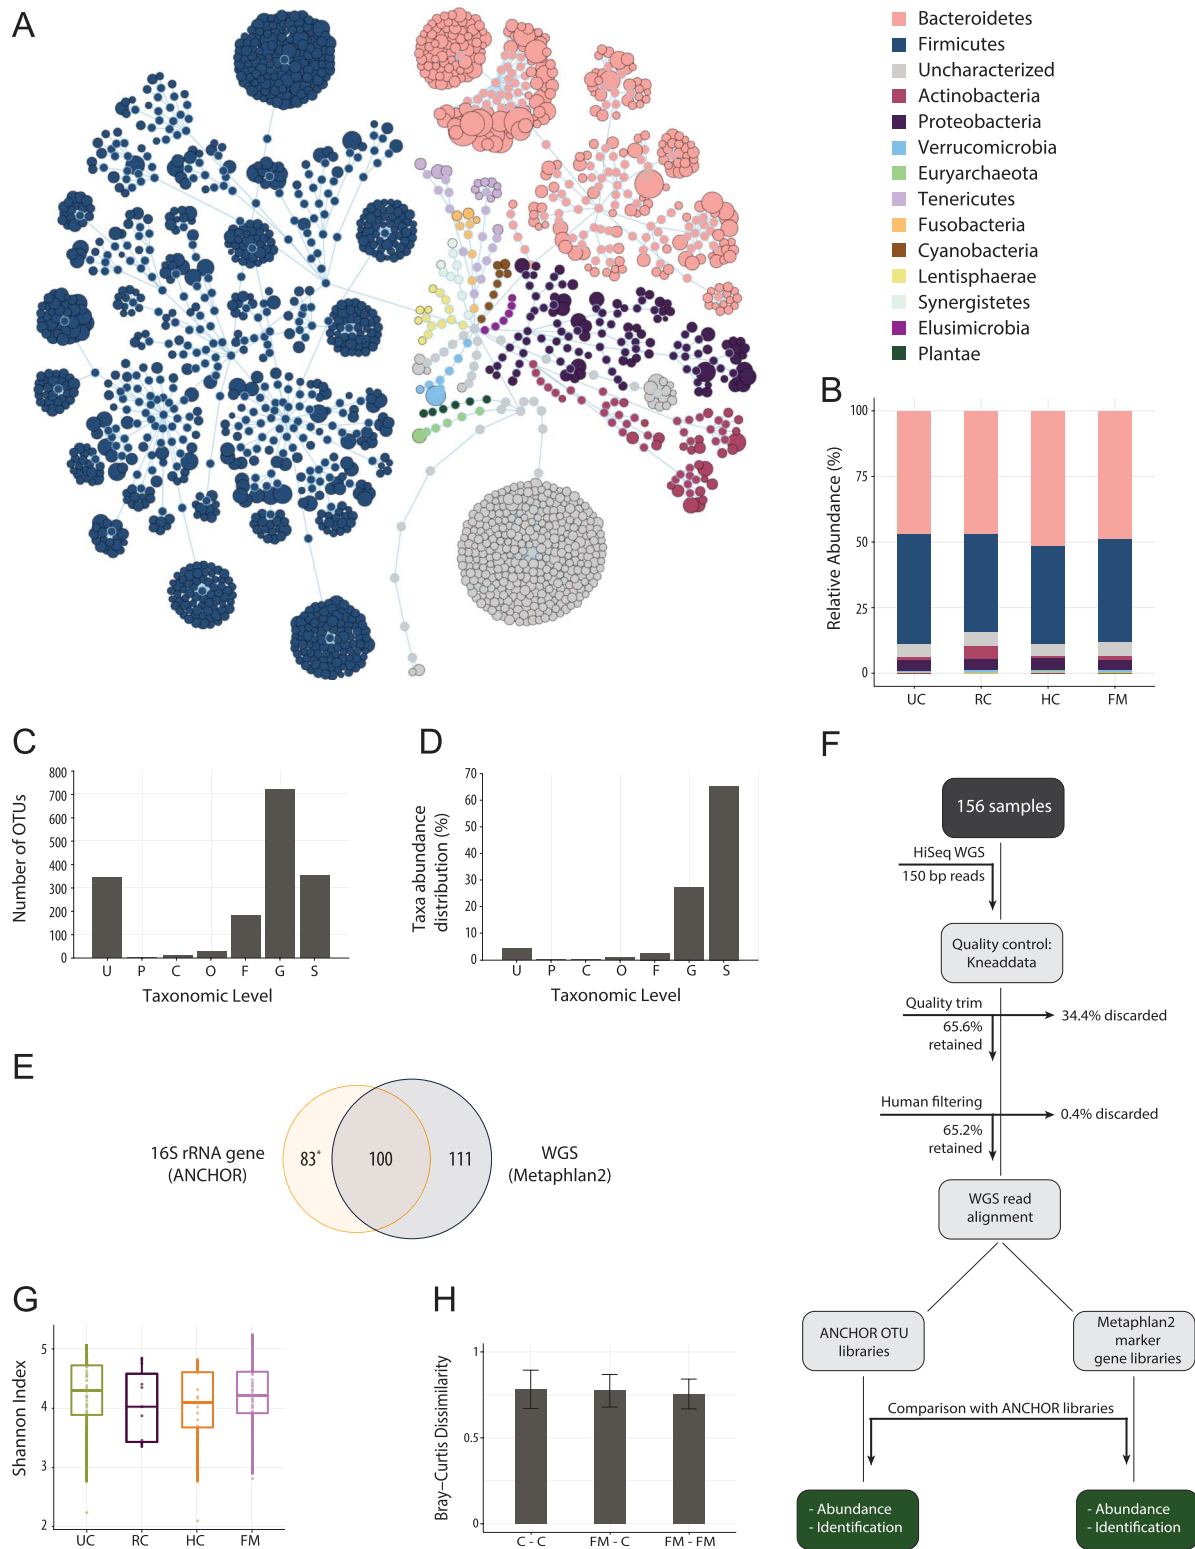

Figure 1. Overall microbiome composition of 156 study participants. (A) Flower diagram of 1620 OTUs colour coded by phyla. An interactive version is available on http://www.computationalgenomics.ca/pub/fibromyalgia_microbiome/flower_diagram/. (B) Phyla-level taxonomic composition of the gut microbiome among FM patients ($n = 77$), relative controls (RC, $n = 11$), household members (HC, $n = 20$), and unrelated controls (UC, $n = 48$). (C) Distribution of OTUs by taxonomic level of identification. (D) Distribution of relative abundance by the level of taxonomic identification. (E) Comparison of Bray–Curtis dissimilarity between all pairs of 156 participants, demonstrating that pairwise distances between FM patients (FM–FM, 1482 pairs) are smaller as compared to distances between pairs of patients–controls (FM–C, 6083 pairs) or controls–controls (C–C, 1560). (F) Comparison of alpha diversity indices for each participant group. (G) Study design flowchart. (H) Comparison of species identification using 16S rRNA genes (ANCHOR; yellow) and WGS (Metaphlan2; blue) technologies. FM, fibromyalgia; WGS, whole-genome sequencing.

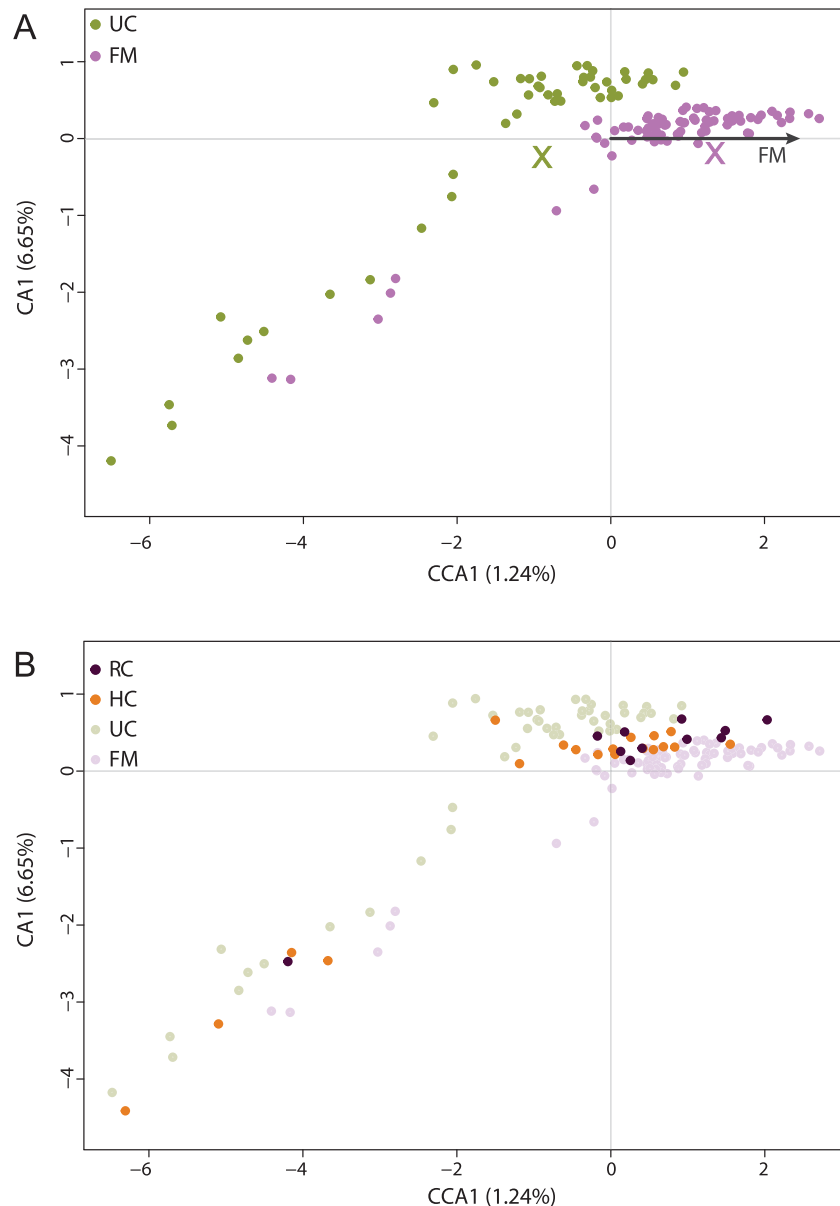

Figure 2. (A) Canonical correlation analysis (x axis) vs principal component analysis (y axis) of taxa abundance (raw counts) in FM patients vs unrelated controls (UC). Amount of explained variance is provided ($P < 0.001$, ANOVA). (B) Relatives (RC) and household controls (HC) cluster midway between FM patients and unrelated controls. ANOVA, analysis of variance; FM, fibromyalgia.

3.6. Microbiome-based machine-learning identification of fibromyalgia patients

To explore the utility of gut microbiome composition in identifying FM patients, we used machine-learning using LASSO (least absolute shrinkage and selection operator) and SVM algorithms to define the OTUs most predictive of the diagnosis of FM (Fig. 5A). The full and sparsity-filtered count tables, as well as OTU subsets (DA and random), were tested to determine the most useful data set for classification. The DA OTU data set yielded the highest diagnostic accuracy. A 10-fold cross-validation (10,000 iterations) yielded 123 DA OTU sets with the highest diagnostic accuracy. LOOCV (leave-one-out cross-validation) identified a set of OTUs that provided the best overall prediction accuracy (AUC-ROC of 87.2%; Figs. 5B and C). Finally, this best predicting OTU set was used in a SVM trained on 90% of participants. The SVM yielded a prediction accuracy of ROC-

AUC 87.8% (Fig. 5D) using cohorts of 10% of participants (100 iterations).

The superior utility of the DA OTU data set reiterates the notion that DA taxa represent a true difference between FM patients and controls. Furthermore, these results suggest that the composition of the microbiome could be indicative of the diagnosis of FM.

4. Discussion

The overall population structure and diversity of the gut microbiome in patients with FM and a matched cohort of healthy controls was relatively similar. When explored at a higher resolution, however, gut microbiome composition showed significant alterations in FM patients. These differences, independently evident using multiple analytic approaches, revealed a distinct pattern of the fecal microbiome in FM. The diagnosis of

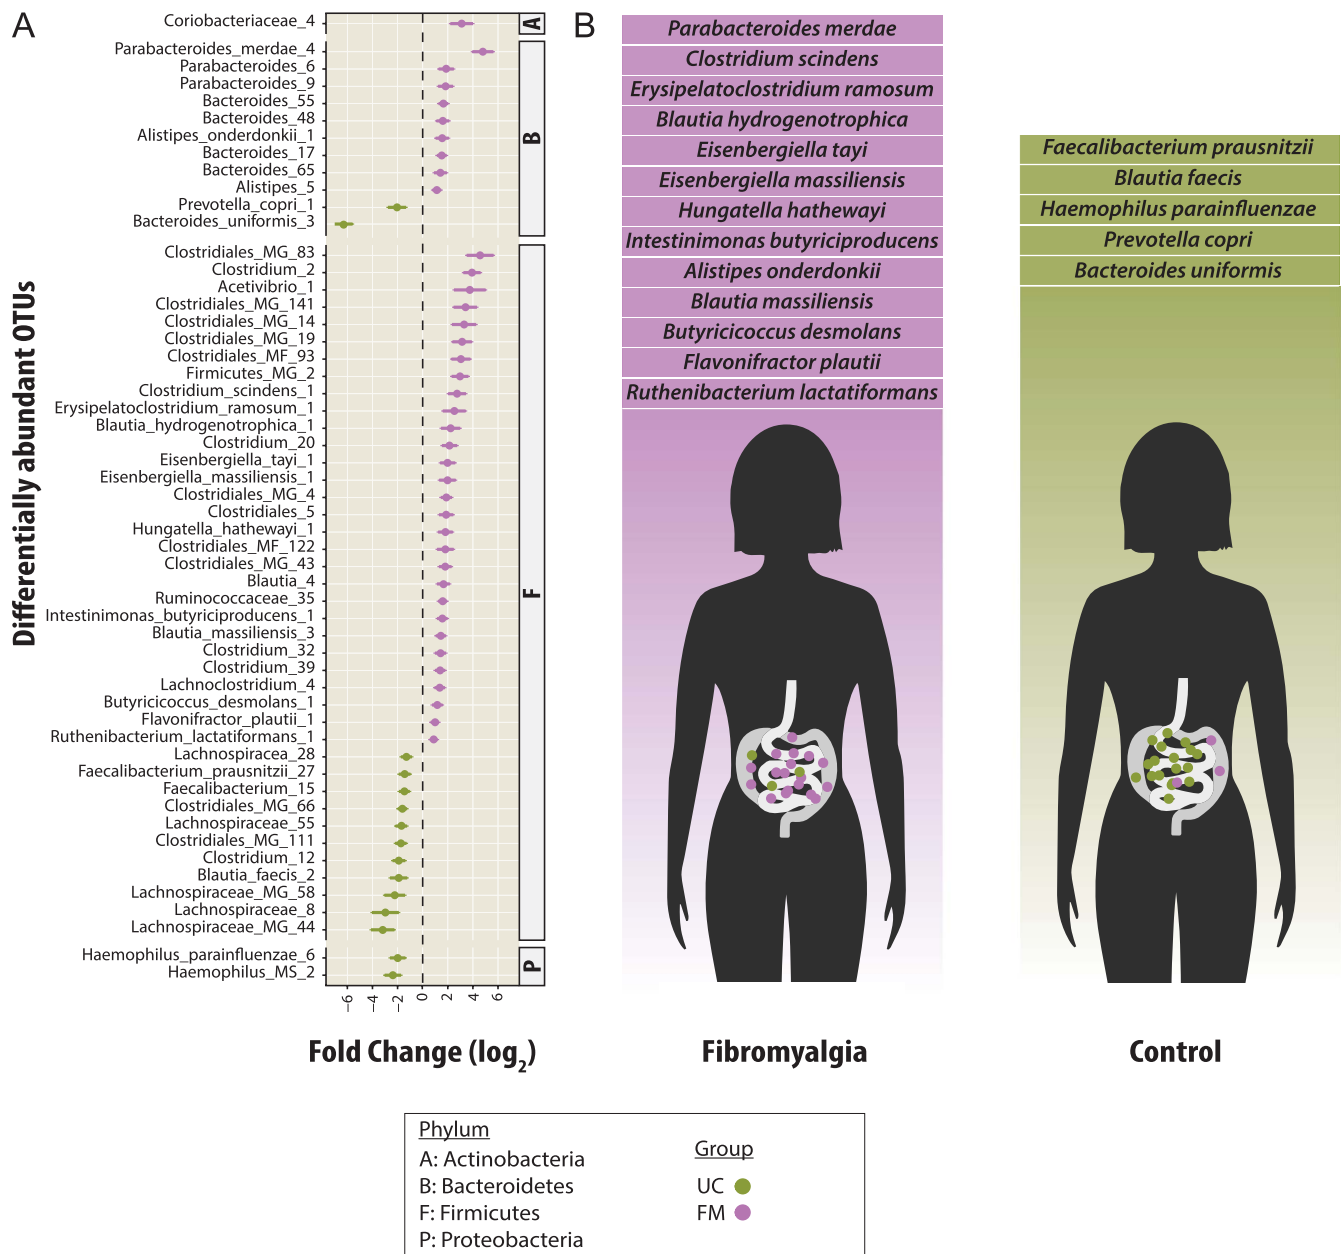

Figure 3. (A) Differentially abundant OTUs between the FM and unrelated control groups. Fold change (FC \log_2) denotes relative differences in relative abundance between groups (DESeq2). Species are grouped by phylum per comparison. (B) A diagram of species-level differentially abundant bacteria in FM patients (left) and in healthy controls (right). FM, fibromyalgia; OTU, operational taxonomic unit.

FM and its clinical features (pain, fatigue, and cognitive symptoms) explained more microbiome variance than did any other covariate, including demographic, anthropometric, and dietary variables, as well as comorbidities and medication consumption.

We observed a quantitative association between the abundance of several taxa and the severity of FM-related symptoms, including pain intensity, pain distribution, fatigue, sleep disturbances, and cognitive symptoms. The abundance of these taxa correlated selectively with disease-related symptoms, but not with disease-independent variables.

Having established that gut microbiome is altered in FM patients, LASSO machine-learning algorithm showed high prediction accuracy of patients from controls, based only on individual microbiome features.⁶⁷ Further study, including larger

cohorts, greater ethnic sampling, and cross-cohort assessment, is required before a confident contribution can be made to improved FM diagnostics; however, the ability of our model to accurately identify FM patients in this study indicates that gut microbiome may have the potential to contribute to the clinically challenging diagnosis of FM.

When considering the 19 specific species identified as significantly DA between FM patients and unrelated control participants, there was a broad range in how well characterised these species were. Those species putatively depleted (lower in relative abundance) in FM were relatively well characterised and included *F. prausnitzii*, *B. uniformis*, *P. copri*, and *Blautia faecis*. *F. prausnitzii* is one of the most abundant and well-studied butyrate-producing bacteria in the human gut.⁴⁵ This species has been reported to be depleted in multiple intestinal diseases and was

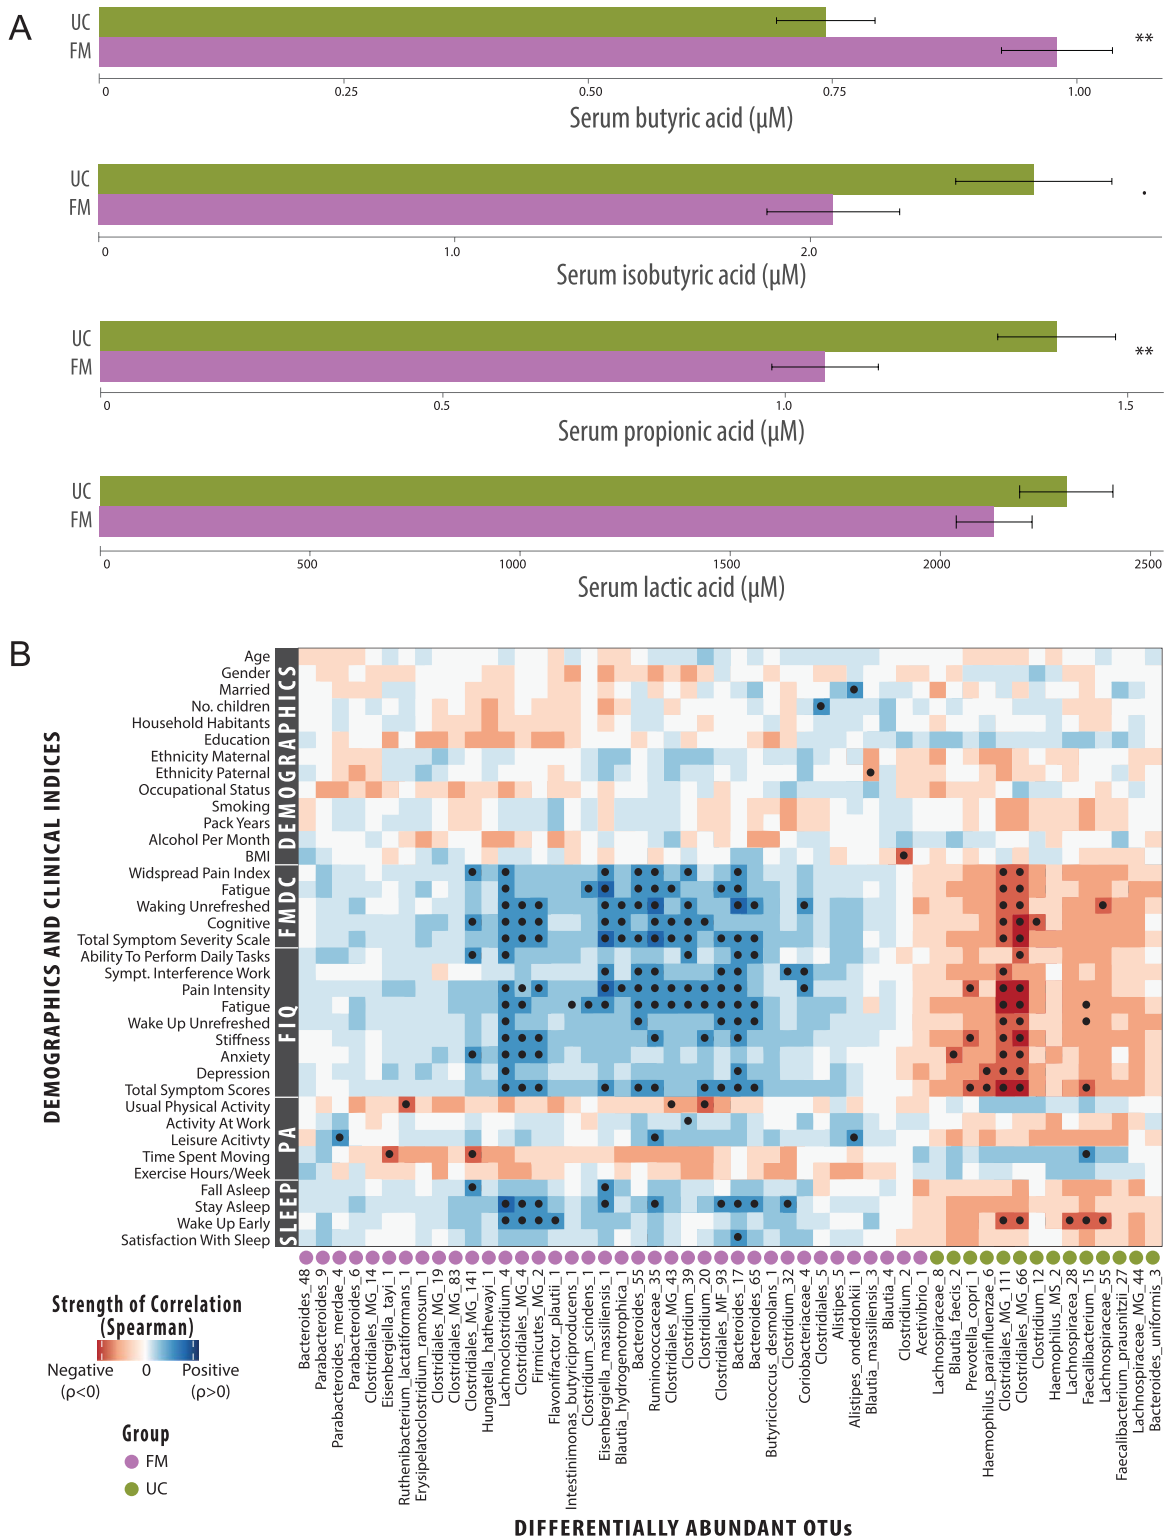

Figure 4. (A) Serum concentrations of butyric acid, isobutyric acid, propionic acid, and lactic acid (ANOVA $**P < 0.01$, $P < 0.1$). (B) Abundance of some DA OTUs is associated with clinical indices: Heat map of a univariate Spearman correlation matrix between DA taxa abundance (\log_2 ; x-axis) vs covariates (y-axis): demographics and anthropometrics; disease severity metrics (FMDC: 2016 FM diagnostic criteria); quality of life scores (FIQ); physical activity measures (PA); and sleep quality (sleep) scores. Heat map is sorted base on a hierarchical clustering of DA OTUs. Blue shades indicate positive correlations, whereas red shades indicate negative correlations ($-0.5 < \rho < 0.5$). Statistically significant correlations are marked by a black dot (Benjamini–Hochberg FDR < 0.05). Note the selective significant correlation of taxa abundance with symptom severity but not with other independent variables. ANOVA, analysis of variance; DA, differentially abundant; FDR, false discovery rate; FIQ, FM Impact Questionnaire; FM, fibromyalgia; OTU, operational taxonomic unit.

therefore suggested as a potential marker for gut disorders. Within the gut, *F. prausnitzii* has been reported to exert antinociceptive as well as anti-inflammatory effects^{57,78} and to

enhance the intestinal barrier function.⁴⁵ Similar to our observations, *F. prausnitzii* was also reported to be depleted in patients with CFS.⁶⁰

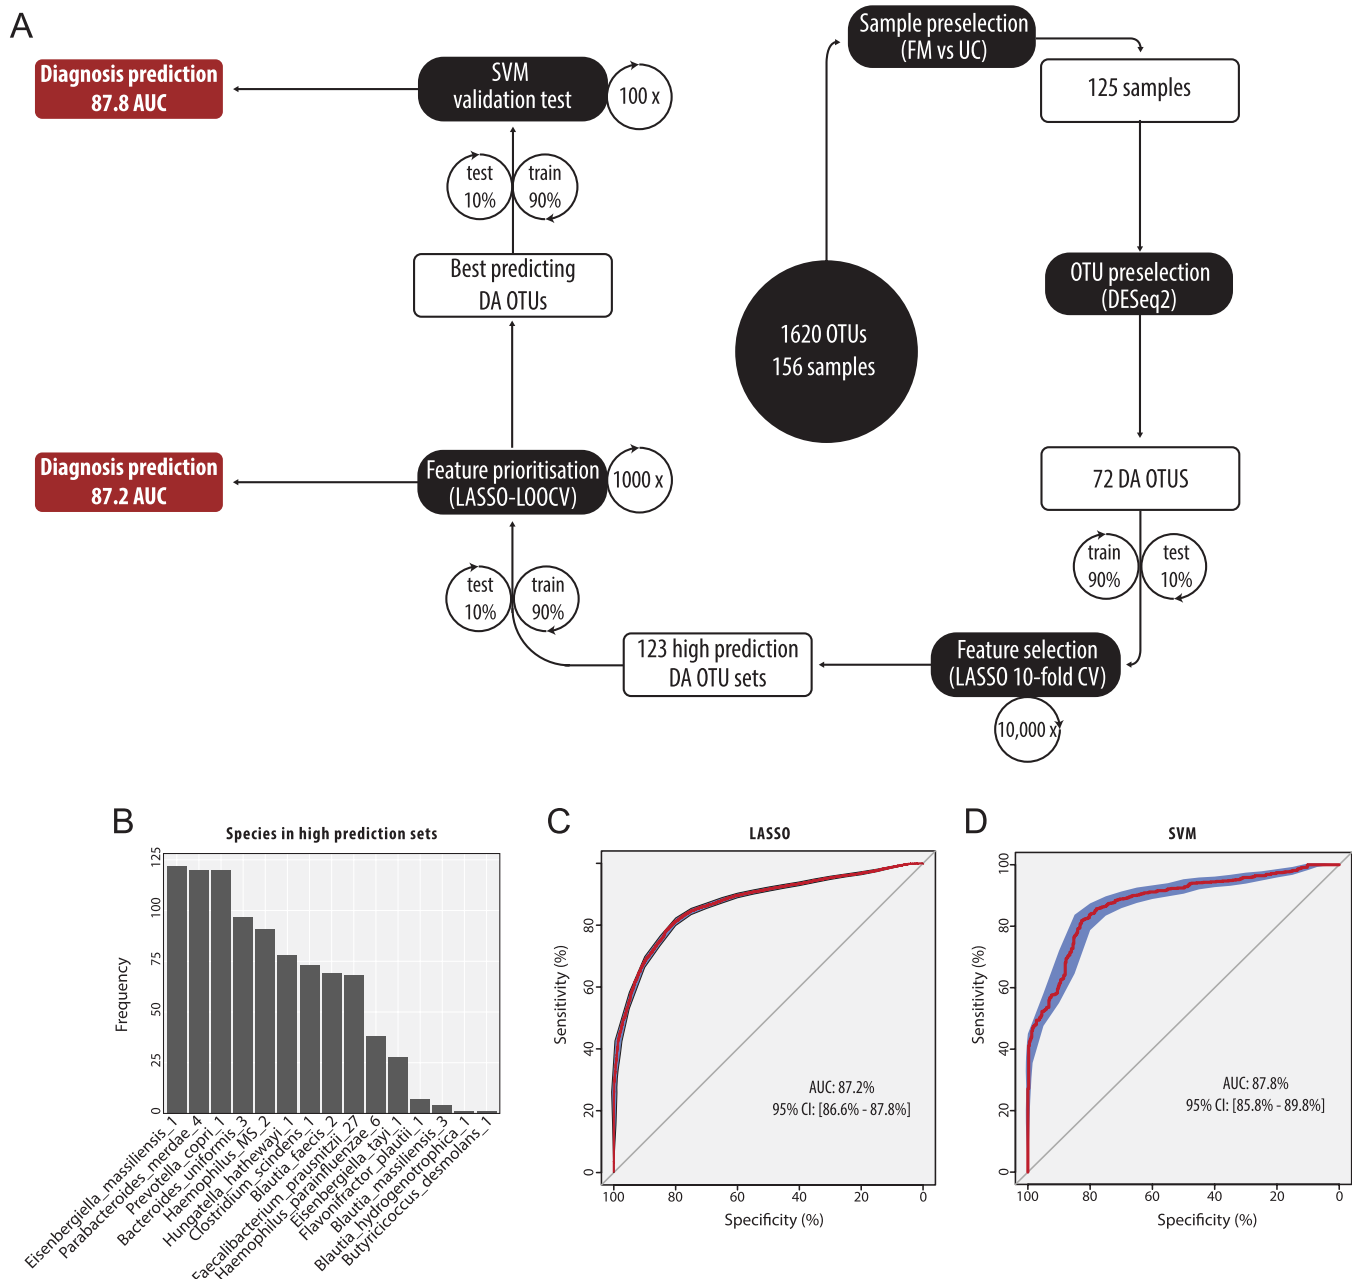

Figure 5. Machine-learning classifier algorithm: (A) Two-step LASSO⁹⁵ workflow adapted from Bollepalli et al.⁹ Operational taxonomic units that resulted in the best prediction accuracy in LASSO were used in a support vector machine (SVM). (B) Species-level annotated OTUs most often selected by LASSO. (C) Receiver operating characteristic curve for 1000 iterations of LASSO-LOOCV feature prioritisation using 123 previously selected OTU sets. (D) Receiver operating characteristic curve for 100 iterations of SVM validation test using most important group of OTUs (group_103). The model was trained on 90% of the initial number of samples and tested on the remaining. AUC, area under the curve; CV, cross-validation; LOOCV, leave-one-out cross-validation; OTU, operational taxonomic unit; ROC, receiver operating characteristic.

B. uniformis is one of several species that have recently been reported as having altered relative abundance in patients with inflammatory arthritis, along with *Haemophilus parainfluenzae*, *P. copri*, and others.⁹⁵ *B. uniformis* and *H. parainfluenzae* were detected in synovial tissues of osteoarthritic joints, whereas *P. copri* and *H. parainfluenzae* were detected in rheumatoid arthritis synovial fluid. *P. copri* is believed to mediate inflammatory response through Th17 activation,^{36,42} and was also shown to induce arthritis in an animal model of arthritis-prone mice.⁵⁰ In this study, these species were found in lower abundance in FM patients. Although FM is often considered to be a rheumatologic disease, it seems that at least some species previously found at

higher abundance in inflammatory rheumatic diseases are depleted in FM.

In contrast to the depletion of butyrate producers *F. prausnitzii* and *B. uniformis* in FM patients, we observed significant higher relative abundance of a number of other known intestinal butyrate producers: *I. butyriciproducens*, *F. plautii*, *B. desmolans*, *E. tayi*, and the recently identified *E. massiliensis*.^{1,3,10,12,37,81,87} Alterations in butyrate- and propionate-metabolizing species were further supported by alterations in serum levels of these short-chain fatty acids. Coherent with this putative shift in the butyrate-producing community of FM patients, *Parabacteroides merdae* was also significantly higher in relative abundance in FM patients.

Recently, *P. merdae* has been reported by Olson et al. to be one of 2 key mediators of the antiepileptic effect of the ketogenic diet⁶³: in a mouse model, ketogenic diet can drive an increase in the abundance of *P. merdae*, which in turn, by regulation of amino acid γ -glutamylase, leads to an increase in hippocampal γ -aminobutyric acid (GABA)/glutamate ratio. The increase in the inhibitory to excitatory neurotransmitter ratio in the brain is believed to protect against seizures. The second key mediator species of the ketogenic diet effect on seizures reported by Olson et al. was *Akkermansia muciniphila*, which in our cohort was also found at higher abundance in FM patients, although this observation did not reach statistical significance ($P = 0.042$, Benjamini–Hochberg FDR = 0.27).

Clostridium scindens and *B. desmolans*, 2 bacterial species capable of converting cortisol to androgens by 20 α -hydroxysteroid dehydrogenase activity,^{8,18,59,72,80} were found in higher abundance in FM patients. Interestingly, abnormal regulation of hypothalamic-pituitary-adrenal axis has been reported in FM patients, although the direction of dysregulation is controversial.^{20,79}

Fibromyalgia shares clinical features with several syndromes, including IBS, CFS, and IC. Specific alterations in gut microbiota were reported in all these syndromes (IBS,^{69,70,82,97} CFS,⁶⁰ and IC⁹). Although several taxa, found here to be DA in FM, were also reported to be DA in other overlapping syndromes, other taxa seem to be unique to FM. As an example, *C. scindens* was found at higher abundance both in FM and in CFS. *H. parainfluenzae* and *F. prausnitzii* were found at decreased abundance in FM and in CFS, and the latter was also reported to be depleted in IC patients.⁹ Several genera, including *Bacteroides*, *Parabacteroides*, and *Clostridium* were found DA both in IBS and in FM (independent of IBS).^{70,82,97} Nevertheless, a few taxa showed an inverse differential abundance pattern: eg, *P. merdae*, significantly higher in FM, was reported to be depleted in CFS.⁶⁰ Furthermore, FM is associated with a high frequency of mental health comorbidity, mainly anxiety and depression affecting 40% to 80% of individuals.^{2,31} Anxiety, depression, and emotional stress have been associated with alterations in gut microbiome both in the general population⁴⁰ and in the context of specific other diagnoses. Recent research by Peter et al. (2018) has revealed the potential importance of mental health as a factor in IBS, suggesting that further cross-disciplinary research is needed to fully understand the microbiome differences identified here.⁶⁹ It thus seems that FM shares some microbiome characteristics with several overlapping syndromes, while retaining some unique features.

In this study, effort was made to validate the diagnosis of each patient by a thorough medical evaluation by experienced pain specialists, thus excluding over 15% of interviewed patients. We consider the meticulous characterization of patient phenotypes, an important strength of this study. A full dietary intake evaluation was completed for nearly 80% of participants and analyzed by a team of nutritionists. To the best of our knowledge, this type of in-depth evaluation is not routinely performed in similar studies. Finally, each participant underwent a full medical, including documentation of their comorbidities (with a specific evaluation for IBS), medication consumption, physical activity, and sleep. These measures resulted in a well-balanced case-control cohort, almost identical in demographics, anthropometrics, comorbidities, nonpain medication intake, and dietary intake. Furthermore, the extent of collected data allowed us to evaluate the effect of each variable on the observed variance in microbiome composition and to detect potential confounding factors. The cohort of 156 participants provided sound statistical power. We have used

2 sequencing methods—16S rRNA gene amplification and WGS metagenomics analyses—each with its own advantages and drawbacks, to allow for an independent validation of the microbiome composition. The combination of large cohort size with high depth of coverage allowed for the identification of low-prevalence DA species, such as *I. butyriciproducens*. Targeted serum metabolomics allowed for an independent support of some of the alterations observed in the gut microbiome. Results of this study should be considered in light of several limitations: first, the symptoms of FM include chronic pain, fatigue, and other somatic symptoms, precluding the attribution of specific microbiome alteration to a specific clinical presentation. Second, over 90% of participants self-reported as Caucasians, possibly not reflecting microbiome patterns in other ethnic groups. Third, participants' diagnoses were recorded based on a systematic clinical interview, which could potentially lead to underdiagnosis. Mental health conditions may be underrepresented in FM patients (supplementary Table 5, available at <http://links.lww.com/PAIN/A839>) as compared to self-reported symptoms (supplementary Table 2, participants were not evaluated by a mental health care specialist, available at <http://links.lww.com/PAIN/A839>). Finally, this study was designed to find an association between microbiome composition and FM, not allowing for direct conclusions regarding causality or mechanisms of action to be drawn.

The results reported here are, to the best of our knowledge, the first to demonstrate gastrointestinal tract microbiota alteration in patients with somatic (nonvisceral) pain in general, and FM in particular. Some of the DA taxa reported here are known to be involved in metabolic pathways whose effect on symptoms of FM is biologically plausible. Moreover, there seems to be a quantitative correlation between the abundance of several taxa and symptom severity. Finally, DA taxa in FM patients share some commonalities with overlapping dysfunctional syndromes—IBS, CFS, IC—while retaining some unique DA taxa.

Results of this study provide evidence for alterations of gut microbiome in FM. Further studies are needed to measure possible microbiome changes in other chronic pain conditions, and to explore potential causal correlations between the gut microbiome and FM. Our findings may offer important opportunities to improve our understanding of FM, aid in its diagnosis, and perhaps outline future therapeutic modalities. First, exploring the mechanisms by which the gut microbiota may affect nociception could offer new insights into the pathogenesis and pathophysiology of FM, and possibly suggest leads to explore the possible effects of trigger events, personal susceptibility, and individual prognosis. Second, the accuracy of microbiome-based machine learning classification suggests that the microbiome holds the potential to aid in the diagnosis of FM in the future. Finally, if a causal relationship between gut microbiome alterations and FM is established, the way may be paved for the development of new treatment modalities targeting this fascinating community of intestinal microorganisms.

Conflict of interest statement

The authors have no conflicts of interest to declare.

Acknowledgments

The authors acknowledge the generous financial support of the Louise and Alan Edwards Foundation. The authors thank the Israeli Society for Musculoskeletal Medicine for their financial support. The authors would like to thank Mrs Sylvie Toupin, Mrs Linda Ferguson,

Dr Pierre Lepage (Génome Québec), Dr Rupa Mandal (TMIC), Ms Audrey Moyen, and Mr Stéphan Attara for their invaluable help in the realization of this project. The authors are grateful to L'association de la Fibromyalgie de Montréal and to all participants for their partnership. The authors thank David Anderson for advising on figure design. DNA sequencing was performed by Génome Québec, Montreal. Metabolite analysis was performed by the metabolomic innovation centre (TMIC), Edmonton, Alberta. The Canadian Center for Computational Genomics (C3G) is a Genomics Technology Platform (GTP) supported by the Canadian Government through Genome Canada. Author contributions: A. Minerbi and Y. Shir conceived, designed, and supervised the study. Y. Shir, A. Minerbi, M.A. Fitzcharles, K. Dewar, and S. Chevalier were involved in the design of the study. A. Minerbi and M.A. Fitzcharles interviewed and evaluated FM patients. A. Anjarkouchian performed the nutritional evaluations. A. Minerbi collected all biological samples. Genomic data was analysed by E. Gonzalez, N.J. Brereton, and A. Minerbi. Dietary analysis was performed by S. Chevalier and A. Anjarkouchian. Metabolomic data was analysed by A. Minerbi. K. Dewar, S. Chevalier, E. Gonzalez, N.J. Brereton, and A. Minerbi were involved in data analysis, evaluation, and integration. The manuscript was written by A. Minerbi, Y. Shir, N.J. Brereton, E. Gonzalez, and S. Chevalier.
